Abstract

Our system treats coreference resolution as an integer linear programming (ILP) problem. Extending Denis and Baldridge (2007) and Finkel and Manning (2008)’s work, we exploit loose transitivity constraints on coreference pairs. Instead of enforcing transitivity closure constraints, which brings $O(n^3)$ complexity, we employ a strategy to reduce the number of constraints without large performance decrease, i.e., eliminating coreference pairs with probability below a threshold $\theta$. Experimental results show that it achieves a better performance than pairwise classifiers.

1 Introduction

This paper describes our coreference resolution system participating in the close track of CoNLL 2011 shared task (Pradhan et al., 2011). The task aims to identify all mentions of entities and events and cluster them into equivalence classes in OntoNotes Corpus (Pradhan et al., 2007a). During the last decade, several machine learning methods for coreference resolution have been developed, from local pairwise classifiers (Soon et al., 2001) to global learning methods (Luo et al., 2004; Ng, 2005; Denis and Baldridge, 2007), from simple morphological, grammatical features to more linguistically rich features on syntactic structures and semantic relations (Pradhan et al., 2007b; Haghighi and Klein, 2009).

Our system supports both local classifiers and global learning. Maximum entropy model is used for anaphoricity and coreference, because it assigns probability mass to mentions and coreference pairs directly. In global phase, instead of determining each coreference pair independently in a greedy fashion, we employ an integer linear programming (ILP) formulation for this problem. Extending (Denis and Baldridge, 2007) and (Finkel and Manning, 2008)’s work, we introduce a loose selection strategy for transitivity constraints, attempting to overcome huge computation complexity brought by transitivity closure constraints. Details are described in section 2.3.

2 System Description

2.1 Mention Detection

Mention detection is a method that identifies the anaphoricity and non-anaphoricity mentions before coreference resolution. The non-anaphoric mentions usually influence the performance of coreference resolution as noises. Coreference resolution can benefit from accurate mention detection since it might eliminate the non-anaphoric mentions. We take mention detection as the first step, and then combine coreference classifier into one system.

Total 70 candidate features are used for mention detection, including lexical, syntactic, semantic features (Ng and Cardie, 2002). Features are selected according to the information gain ratio (Han and Kamber, 2006)

\[
\text{GainRatio}(A) = \frac{\text{Gain}(A)}{\text{SplitInfo}(A)}
\]

The top 10 features with highest gain ratio are: string match, head word match, all uppercase, pronoun, starting with article, number, following preposition, nesting in verb phrase, nesting in preposition,
and starting with definite article. Many string features that cannot be calculated by gain ratio method are also added.

2.2 Coreference Determination

For coreference determination, we first build several baseline systems with different training instance generation methods and clustering algorithms. These strategies are shown below. Detailed description can be found in Ng (2005).

- training instance generation methods: McCarthy and Lehnerts method, Soon et al.’s method, Ng and Cardie’s method.
- clustering algorithms: closest-first clustering, best-first clustering, and aggressive merge clustering.

Overall 65 features are considered in our system. Features are extracted from various linguistic information, including:

- distance: sentence distance, minimum edit distance (Strube et al., 2002)
- lexical: string match, partial match, head word match (Daumé III and Marcu, 2005)
- grammar: gender agreement, number agreement (Soon et al., 2001)
- syntactic: same head, path (Yang et al., 2006)
- semantic: semantic class agreement, predicate (Ponzetto and Strube, 2006; Ng, 2007)

Combining different training instance generation methods and clustering algorithms, we get total 9 baseline systems. For each system, we use a greedy forward approach to select features. Starting from a base feature set (Soon et al., 2001), each feature out of the base set is added one by one according to the performance change on development data. Finally, the procedure is ended until the performance is not improved. The baseline system with best performance is selected for further improvement.

2.3 ILP with Loose Transitivity Constraints

Previous systems usually take coreference resolution as binary classification problem, and build the coreference chain by determining each coreference pair independently. The binary classifier is easily implemented, but may cause inconsistency between coreference pairs. Several work have been developed to overcome the problem, e.g., Bell trees (Luo et al., 2004), conditional random fields (McCallum and Wellner, 2004) and reranker (Ng, 2005).

Denis and Baldridge (2007) proposed an ILP formulation to find the optimal solution for the problem. It utilizes the output of other local classifiers and performs global learning. The objective function for their conference-only model takes the form:

$$
\min \sum_{(i,j) \in M^2} c_{i,j} \cdot x(i,j) + \bar{c}_{i,j} \cdot (1 - x(i,j))
$$

where $c_{i,j} = -\log(P_C)$, $\bar{c}_{i,j} = -\log(1 - P_C)$. M is the candidate mention set for each document. $P_C$ refers to the probability of coreference link between two mentions produced by our maximum entropy model, and $x(i,j)$ is a binary variable that is set to 1 if two mentions are coreferent, 0 otherwise.

However, as Finkel and Manning showed, D&B’s coreference-only model without transitivity constraints is not really necessary, because they only select the coreference links with probability $P_C > 0.5$. Klenner (2007) and Finkel and Manning (2008)’s work extended the ILP framework to support transitivity constraints. The transitivity constraints are formulated as

$$
\forall i, j , k \in M (i < j < k)
$$

$$
x(i,j) \geq x(j,k) + x(i,k) - 1
$$

$$
x(j,k) \geq x(i,j) + x(i,k) - 1
$$

$$
x(i,k) \geq x(i,j) + x(j,k) - 1
$$

These constraints ensure that when any two corefrent links (e.g., $x(i,j)$, $x(i,k)$) among three mentions exist, the third one $x(j,k)$ must also be a link. However, these constraints also bring huge time and space complexity with $n^3$ constraints (n is number of candidate mention set M, which is larger than 700 in some documents), and cannot be solved in a restricted time and memory environment. We introduce a loose method to eliminate conference links...

In the paper we mainly take noun phrases (NPs) and pronouns as candidate mentions, and ignore other phrases since more than 91% of the mentions are NPs and pronouns.

#### 3 Experiments and Analysis

In the paper we mainly take noun phrases (NPs) and pronouns as candidate mentions, and ignore other phrases since more than 91% of the mentions are NPs and pronouns.

##### 3.1 Mention Detection

We observe that the ratio of positive examples and negative examples is about 1:3 in training data. To balance the bias, we propose a ratio control method which sets a ratio to limit the number of negative examples. Our system will select all positive examples, and part of negative examples according to the ratio. By tuning the ratio, we can control the proportion of positive and negative examples. With different ratios for negative feature selection, the results on development data are shown in table 1.

From table 1, we can see that as the ratio increases, recall becomes smaller and precision becomes larger. Small threshold means less negative examples are generated in training procedure, and the classifier tends to determine a mention as positive. Finally, we choose the ratio 0.6 for our model because it gets the best F-value on the development data.

##### 3.2 Coreference Resolution

Our system participates in the close track with auto mention and gold boundary annotation. The performance is evaluated on MUC, B-CUBED, CEA(M), CEA(E), BLANC metrics. The official metric is calculated as $(MUC + B^3 + CEA(M)) / 3$.

Table 2 summarizes the performance of top 4 of 9 baseline systems with different training instance generation methods and clustering algorithms on development data. In the table, TIGM means training instance generation method, and CA denotes clustering algorithm, which includes C as closest-first, B as best-first, and A as aggressive-merge clustering algorithm. The results in Table 2 show that the system with Soon’s training instance generation method and best-first clustering algorithm achieves the best performance. We take it as baseline for further improvement.

In ILP model, we perform experiments on documents with less than 150 candidate mentions to find the suitable probability threshold $\theta$ for loose transitivity constraints. There are total 181 documents meeting the condition in development data. We take two strategies to loose transitivity constraints: (I) formula 1 and 2, and (II) formula 2 only. Glpk package is used to solve our ILP optimization problems.

Table 3 shows that as threshold $\theta$ increases, the running time reduces dramatically with a small performance decrease from 49.06 to 48.88. Strategy I has no benefit for the performance. Finally strategy II and $\theta = 0.06$ are used in our system.

We also combine mentions identified in first phase into coreference resolution. Two strategies are used: feature model and cascaded model. For feature model, we add two features which indicate whether the two candidate mentions of a coreference pair are mentions identified in first phase or not. For cascaded model, we take mentions identified in first phase as inputs for coreference resolution. For ILP

model, we perform experiments on coreference-only system with our loose transitivity constraints. The results on development data are shown in Table 4.

In Core Quad 2.40G CPU and 2G memory machine, our ILP model can optimize one document per minute on average. From Table 4, we can see that the ILP model achieves the best F-value, implying the benefit of our algorithm. It also shows that traditional coreference resolution methods combining mention detection decrease the performance. For restricted time deadline, other constraints strategies (Klenner, 2007) and joint anaphoricity-coreference ILP model are not used in our system. It would be in our future work.

### 3.3 Test

Table 5 shows the performance of our system for both development and test data, with auto mention and gold boundary annotation.

The results in Table 5 show that in auto mention annotation, the performance on test data is a little bit better than development data. The reason might be that the system on test data uses more data to train, including development data. A phenomenon surprises us is that the performance on test data with gold annotation is less than on development data, even than auto annotation. It turns out that the mistake is made because we confuse the definition of gold boundaries as gold mentions, which are “all” and “only” mentions in coreference chains.

### 4 Conclusion

In this paper, we present a coreference resolution system which employs an ILP formulation for global optimization. To reduce computation complexity, our system employs loose transitivity constraints to the ILP model. Experimental results show that it achieves a better performance than pairwise classifiers.
